## Abstract

This article tackles the multi-trip vehicle routing problem with time windows and limited duration. A trip is a timed route such that a succession of trips can be assigned to one vehicle. We provide a two-phase exact algorithm to solve it. The first phase enumerates possible ordered lists of client matching trip maximum duration criterion. The second phase uses a Branch and Price scheme to generate and choose best set of trips to visit all customers. We propose a set covering formulation as the column generation master problem, where columns (variables) represent trips. The sub-problem selects appropriate timing for trips and has a pseudo-polynomial complexity. Computational results on Solomon's benchmarks are presented. The computational times obtained with our new algorithm are much lower than the ones obtained in the sole exact algorithm previously published on this problem.

**Keywords :** Vehicle routing, Time windows, Multi-trip, Column Generation, Dynamic programming, Branch and Price

# 1 Introduction

The Multi-Trip Vehicle Routing Problem with Time Windows (MTVRPTW) is a variant of the classical Vehicle Routing Problem with Time Windows (VRPTW) where vehicles can be scheduled more than one trip within a workday or planning time horizon. The multi-trip feature is needed when the vehicles fleet size is limited. In this study, we consider a special case of the MTVRPTW, called MTVRPTW-LD, where trips (routes) have a limited duration. Motivations to impose this duration limit can be management issues, e.g. limiting the maximum driving time for drivers, or can follow from the nature of transported goods, e.g. delivering perishable goods.

This problem was addressed first in Azi et al. (2007) and Azi et al. (2010). In Azi et al. (2007), the authors proposed an exact method for the single vehicle case. The multi-vehicles variant is considered in Azi et al. (2010) and updated numerical results are given in Azi (2010). We describe in the present article a new exact method for this latter problem. This method is based on Azi's investigations and on our own works on MTVRPTW reported in Hernandez et al. (2009). Using the same instances as in Azi (2010), which are based on Solomon's - Solomon (1987) - we show that the new algorithm allows large improvements in terms of computing times.

This article is organized as follows. The following section is devoted to related works on Vehicle Routing Problem with Time Windows, more specifically on the multi-trips variant problem and on the strategies to solve it. The principle of column generation used in Branch and Price schemes is described in the same section. In section 4, we present our new exact method for MTVRPTW-LD, which is composed of two phases like in Azi et al. (2010). In section 5, consistently with the choice made in Azi et al. (2010) and Azi (2010), we present results for Solomon benchmark instances, including analysis of effects of size of customer time windows and trip max duration on solutions and performance, and compare these with results obtained in Azi (2010). Following sections are devoted to general discussion, conclusion, and perspectives.

## 2 Literature review

As Azi et al. (2007), we note that papers about VRPTW with limited fleet and multi-trip are scarce in the literature. Most of the few works reported so far on solving this problem involved metaheuristics.

### 2.1 Multi-trip vehicle routing problem

As far as we know, Fleischmann (1990), as cited by Battarra et al. (2009), is the first study including the multi-trip idea in the vehicle routing problem without Time Windows. The author used a savings based algorithm to construct the routes and a bin packing heuristic to combine them on vehicles. The same principles have been used in Taillard et al. (1996). In their study, routes are constructed by a Tabu search algorithm. According to Sen and Bülbül (2008), the study in Brandão and Mercer (1998) is about a rich vehicle routing problem with multi-trips and many additional considerations like time windows, heterogeneous fleet, maximum legal driving time per day for drivers, unloading time of vehicles, etc. The authors developed a tabu search to solve this problem. In Sen and Bülbül (2008) is also mentioned the multi-phase algorithm reported in Petch and Salhi (2003), which can be considered as the combination of two approaches mentioned in Taillard et al. (1996) and Brandão and Mercer (1998). Other works analysed in Sen and Bülbül (2008) include Olivera and Viera (2007), a method based

on an adaptive memory procedure, Salhi and Petch (2007) which involves a genetic algorithm to solve the MTVRPTW, and Alonso et al. (2008). In this latter paper is studied the case of periodic vehicle routing problem with time windows and multi-trips, in which one customer can be served 1 to  $t$  times in a planning period, and in which split and delivery is allowed. A tabu search is applied to solve the problem. In Battarra et al. (2009), the authors decompose the MTVRPTW into two easier problems, and create two heuristics to solve them. The first heuristic deals with the creation of routes and the second with a bin packing problem. The complete algorithm is iterative and is based on a self adaptive guidance strategy which enforces the route heuristic to compute only the routes that can improve the solution.

## 2.2 Exact method for vehicle routing problem with time windows and multi-trips

To our knowledge, the first exact method on MTVRPTW-LD was proposed in Azi et al. (2007). The authors considered the case of the delivery of perishable goods with a single vehicle. They created an algorithm with two phases of dynamic programming. In the first phase, dynamic programming is used to generate all non-dominated routes. A graph where the nodes represent the routes obtained in phase 1 is then created. Transitions of this graph represent the possible successions of routes. Note that the size of routes' graph is bounded thanks to the limit on route duration. In the second phase, dynamic programming is used to generate the working day for the vehicle from the routes' graph and with the dominance rule given in Feillet et al. (2004). In Azi et al. (2010), the authors considered the same problem but with an homogeneous fleet instead of a single vehicle. The first phase is similar to the single vehicle case. The second phase uses the Column Generation technique to generate the working day for each vehicle. In the Column Generation scheme, the pricing problem is in fact similar to the ESPPRC used in the second phase of Azi et al. (2007), besides cost modification implied by dual variables. Note that in both single and multi-vehicle cases, the graph of non-dominated routes is generated only once.

As our work presented here is also based on Column Generation and the Branch and Price scheme, we recall hereafter how it has been applied so far to VRPTW.

## 2.3 Column Generation

The Branch and Price is a Branch and Bound where the lower bound is computed by Column Generation. This technique is used to solve huge mixed integer programs. Column Generation consists in decomposing the whole problem into two simpler problems, called master problem and sub-problem. These two problems are solved iteratively. This process stops when there is no longer a solution for the sub-problem.

The first application of this method on the VRPTW is given in Desrochers et al. (1992). In the VRPTW case, the master problem is a set covering problem, and the sub-problem corresponds to an elementary shortest path problem with resource constraints (ESPPRC). The ESPPRC sub-problem is defined over a graph  $G' = (N \cup \{o, d\}, E)$ , where  $N \cup \{o, d\}$  and  $E$  are the sets of nodes and arcs, respectively.  $N$  is the set of nodes for each customer in  $V \setminus \{v_0\}$ . Nodes  $o$  is the node for the depot 0 at the beginning of a route and  $d$  is the node for 0 at the route end. The set  $E$  contains arcs  $(o, j)$ ,  $\forall j \in N$ ; arcs  $(i, d)$ ,  $\forall i \in N$ ; and arcs  $(i, j)$ ,  $\forall i, j \in N$  such that customer  $j$  can be visited after customer  $i$  by at least one feasible route. A cost  $c_{ij}$  is associated with each arc  $(i, j) \in E$ .

Each feasible route is represented by a path in  $G'$ . The following  $|N| + 2$  resource constraints are needed on the ESPPRC, so that time windows are encountered and vehicle capacity is not exceeded: the time  $t$ , the vehicle load  $q$ , and  $V^i$  for each customer  $i \in N$  indicating if the

customer  $i$  has been visited along the path. The resource intervals are the customer time windows for  $t$ ,  $[0, Q]$  for  $q$ , where  $Q$  is the vehicle capacity, and  $[0, 1]$  for each  $V^i$ . This set of resources is denoted by  $R = \{t, q, V^1, \dots, V^{|N|}\}$ .

In order that the Column Generation scheme will produce an exact solution, the ESPPRC needs to be solved exactly. Since the ESPPRC is  $\mathcal{NP}$ -hard (see Dror (1994)), Desaulniers et al. (2008) proposed a metaheuristic alternative to find new columns. When none can be found by the metaheuristic, then the exact algorithm for ESPPRC is called.

### 3 Multi-trip vehicle routing problem with time windows and limited duration

Formally, the MTRVRPTW-LD is defined as follows. Let  $G = (V, A)$  be a directed graph where  $V = \{0, \dots, n\}$  and  $A$  is the set of arcs  $(i, j)$ . 0 represents the depot and  $1, \dots, n$  the customers. A cost  $c_{ij}$  and a travel time  $t_{ij}$  are attached to each arc  $(i, j) \in A$ . The fleet comprises  $U$  vehicles, all with same load capacity  $Q$ . Let  $[0, T]$  be the planning time horizon, and  $t_{max}$  the duration limit of a trip. For each  $i \in \{1, \dots, n\}$  is defined a demand  $d_i$  and a service time  $st_i$ . Each client must be served within a time window  $[a_i, b_i]$  with  $a_i, b_i \in [0, T]$ . However, vehicles can arrive at a client  $i$  earlier than  $a_i$  and wait. The problem is to find a set of trips with the lowest cost and using at most  $U$  vehicles, and such that (i) all customers are served, (ii) two trips cannot be travelled at the same time by the same vehicle, (iii) loads comply with the capacity of vehicles and (iv) time constraints at the clients and depot are met. In this case, the *trip duration* is the elapsed time between the depot departure time, after the vehicle has been loaded, and the arrival time to the last customer of the trip, before the delivery. The schedule of a vehicle must also include, in the *complete trip duration*, the loading time, the service time to last customer and return time to depot.

We can model the MTRVRPTW-LD with the following MIP:

$$\min \sum_{k \in K} \sum_{(i,j) \in A} c_{ij} x_{ij}^k \quad (1)$$

subject to

$$\sum_{\{j \in V | (i,j) \in A\}} x_{ij}^k = \delta_i^k, (i \in V \setminus \{0\}, k \in K) \quad (2)$$

$$\sum_{k \in K} \delta_i^k \geq 1, (i \in V \setminus \{0\}) \quad (3)$$

$$\sum_{\{j \in V | (i,j) \in A\}} x_{ij}^k - \sum_{\{j \in V | (j,i) \in A\}} x_{ji}^k = 0, (i \in V, k \in K) \quad (4)$$

$$\sum_{\{i \in V | (0,i) \in A\}} x_{0i}^k \leq 1, k \in K \quad (5)$$

$$\sum_{(i,j) \in A} d_i x_{ij}^k \leq Q, k \in K \quad (6)$$

$$\alpha^k = \beta \sum_{\{i \in V\}} st_i \delta_i^k, k \in K \quad (7)$$

$$S_i^k + st_i + t_{ij} - S_j^k + Mx_{ij}^k \leq M, (i, j) \in A, i, j \neq 0, k \in K \quad (8)$$

$$S_i^k + st_i + t_{i0} - d_k^{back} + Mx_{i0}^k \leq M, (i, 0) \in A, k \in K \quad (9)$$

$$d_k^{start} + \alpha^k + st_0 + t_{0i} - S_i^k + Mx_{0i}^k \leq M, (0, i) \in A, k \in K \quad (10)$$

$$S_i^k \leq d_k^{start} + \alpha^k + t_{max}, i \in V, k \in K \quad (11)$$

$$\sum_{\{i \in V | (0, i) \in A\}} x_{0i}^k - \sum_{u \in U} \sigma_k^u = 0, k \in K \quad (12)$$

$$\sigma_k^u + \sigma_l^u - y_{kl}^u - y_{lk}^u \leq 1, k, l \in K, k \neq l, u \in U \quad (13)$$

$$1 - y_{kl}^u - y_{lk}^u \geq 0, k, l \in K, k \neq l, u \in U \quad (14)$$

$$d_k^{back} - d_l^{start} + My_{kl}^u \leq M, k, l \in K, u \in U \quad (15)$$

$$a_i \delta_i^k \leq S_i^k \leq b_i \delta_i^k, i \in V, k \in K \quad (16)$$

$$a_0 \leq d_k^{start} \leq b_0, k \in K \quad (17)$$

$$a_0 \leq d_k^{back} \leq b_0, k \in K \quad (18)$$

$$0 \leq d_k^{start} \leq T, k \in K \quad (19)$$

$$0 \leq d_k^{back} \leq T, k \in K \quad (20)$$

$$x_{ij}^k \in \{0, 1\}, (i, j) \in A, k \in K \quad (21)$$

$$y_{kl}^u \in \{0, 1\}, k, l \in K, u \in U \quad (22)$$

$$\sigma_k^u \in \{0, 1\}, k \in K, u \in U \quad (23)$$

$$\delta_i^k \in \{0, 1\}, i \in V \setminus \{0\}, k \in K \quad (24)$$

$$\alpha^k \geq 0, k \in K \quad (25)$$

where  $x_{ij}^k$ ,  $\sigma_k^u$ ,  $y_{kl}^u$ ,  $\delta_i^k$ ,  $S_i^k$ ,  $\alpha^k$ ,  $d_k^{start}$  and  $d_k^{back}$  are the decision variables.  $x_{ij}^k$  indicates if the arc  $(i, j)$  is in trip  $r_k$  or not,  $\sigma_k^u$  indicates if trip  $r_k$  is traveled by vehicle  $u$ ,  $y_{kl}^u$  indicates whether trip  $r_l$  is traveled after trip  $r_k$  by vehicle  $u$  or not,  $\delta_i^k$  indicates if customer  $i$  is visited by trip  $r_k$ . For a customer  $i$  visited by a trip  $r_k$ ,  $S_i^k$  is the starting time of service.  $\alpha^k$ ,  $d_k^{start}$  and  $d_k^{back}$  are the loading time, the starting time of service and the arrival time of trip  $r_k$  to the depot, respectively.

$K$  is the maximal number of trips needed to guarantee the coverage of all client nodes in the optimal solution. In this case,  $K$  is the number of customers.

Constraints (2) and (3) enforce the visit of every customer. Customers are allowed to be visited more than once. This relaxation is valid since, due to triangle inequality of distances, it is not optimal to visit a customer more than once. Constraints (4)-(5) define the trip structure and constraints (6) concern vehicle capacity. Constraints (7) define the vehicle loading time as the sum of the service times of all customers in a trip, multiplied by a given coefficient  $\beta$ . Constraints (8)-(10) and (16)-(18) concern the compliance of trips to time windows constraints. Note that in the solution, subtours are forbidden by previous inequalities. Constraints (19)-(20) concern the respect of planning horizon. Constraints (11) correspond to the deadline constraint for serving a customer. Note that constraints (16) ensure that  $S_i^k$  is set to 0 when customer  $i$  is not in trip  $r_k$ , and, consequently, constraint (11) is automatically satisfied in this case. Constraints (12)-(15) order the routes on available vehicles.

## 4 A new exact method for the MTRPTW-LD

### 4.1 Introduction, formulation and definitions

In practice this formulation is not tractable for any instances of reasonable size and its linear relaxation is very weak. Thus we propose a two-phase algorithm to solve it, where, as in Azi et al. (2010), the first phase enumerates possible routes, and the second phase uses a Branch and Price scheme to choose best covering set of routes. We will require following definitions.

#### Definition 4.1 *Structure*

A structure is an ordered list of customers than can be visited during a trip while satisfying their time constraints. A structure has a cost  $c_k$ , a travel distance  $D_k$  and a minimal complete trip duration  $d_k^{min}$  needed to visit these customers and come back to depot, in this order.

#### Definition 4.2 *Trip timed structure*

A trip timed structure is a structure with a time window  $[A_k, B_k]$  that can be calculated such that  $A_k$  ( $B_k$ , respectively) is the earliest departure time (latest arrival time, respectively) permitting to visit all customers of  $s_k$  and back to the depot with exactly the duration  $d_k^{min}$ . It will be hereafter simply denominated "structure".

#### Definition 4.3 *Trip*

A trip  $r_k$  is defined as a structure  $s_k$  associated to a fixed starting time  $d_k^{start} \geq A_k$ . Because  $d_k^{min}$  is an attribute of structures, the arrival time of a trip  $d_k^{start} + d_k^{min}$  is also known. We will say that a trip has a fixed time position.

### 4.2 Enumeration phase

As long as the duration limit is relatively short, it is possible to generate all the non-dominated structures (see Azi et al. (2010)). This problem is addressed via an approach that exploits an algorithm solving the elementary shortest path problem with resource constraints given in Feillet et al. (2004).

This algorithm consists in extending labels from one node to another through the graph  $G'$  defined in section 2.3. Each label represents a partial feasible path from the depot to one customer. To initialize the labelling process, one label is created on node  $o$ . This label is then extended to all successors of node  $o$ . Nodes are iteratively treated until no new labels are created. When a node is treated, all its new labels are extended towards every possible successor node. Once a label has been extended, its resource intervals are verified and the label is rejected if infeasible.

This basic method generates many labels. In order to decrease the number of generated labels, a label dominance relation is applied during the solution process on the generated labels associated with the same node.

For the classic VRPTW, a path  $k$  from node  $o$  to node  $j$  is labeled with  $L_k$ .  $L_k$  is defined by  $|N| + 4$  parameters represented by the vector  $L_k = \{c_k, j, T_k^t, T_k^q, V_k^1, \dots, V_k^{|N|}\}$ , where  $c_k$  is cost of this partial path,  $j$  is the node to which the label is attached,  $T_k^t$  and  $T_k^q$  are the accumulated values of time and load, respectively, and  $V_k^i = 1$  if node  $i$  is unreachable, 0 otherwise.

The dominance relation for VRPTW is as follows: If  $k$  and  $k'$  are two different paths from node  $o$  to node  $j$  with labels  $L_k$  and  $L_{k'}$ , respectively, then path  $k$  dominates  $k'$  if and only if  $c_k \leq c_{k'}$ ,  $T_k^t \leq T_{k'}^t$ ,  $T_k^q \leq T_{k'}^q$  and  $V_k^i \leq V_{k'}^i$ ,  $\forall i$ .

That is, path  $k$  dominates  $k'$  if its cost  $c_k$  is not greater, does not consume more resource for every resource considered, and every unreachable node is also unreachable for  $k'$ . As stated

in Feillet et al. (2004), it is guaranteed that no potential optimal solution can be eliminated by this dominance relation.

In our case, the problem is not to find an elementary shortest path within the whole graph  $G'$  as it is for the VRPTW case. We need to find an elementary shortest path for each subset of customers that can be visited without violating constraints. This is why we adapted this algorithm, mainly by modifying resources and dominance rules, as explained hereunder.

#### Resources and dominance rule:

First, like in Azi et al. (2007), the cost  $c_{ij}$  on each arc is replaced by  $c_{ij} - (\max_{(i,j) \in A} c_{ij} + 1)$ . The aim is to generate all feasible non dominated routes. In order to do this, we define the labels as follows:

##### Definition 4.4 *Label*.

A path  $p$  from the origin 0 to node  $j$  is labeled with  $L_p = \{c_p, j, h_p, q_p, d_p^{min}, \mathcal{A}_p, \mathcal{B}_p, W_p^1, \dots, W_p^n\}$ , where  $c_p$  is the reduced cost of this path,  $h_p$  and  $q_p$  are the values of time and load resources, respectively, accumulated along this path;  $d_p^{min}$  is the minimal trip duration of the path represented by  $L_p$ ;  $\mathcal{A}_p$  and  $\mathcal{B}_p$  are the start and end of the label time window as specified in definition 4.2; and  $W_p^i = 1$  if node  $i$  is visited by  $L_p$ , 0 otherwise.

During the extension of label  $L_p$  from a node  $i$  to  $j$ , to obtain  $L_{p'}$ , the label resources are updated as follows:

- $c_{p'} = c_p + c_{ij}$  where  $c_{ij}$  is the cost of arc  $(i, j)$
- $h_{p'}$  is calculated by adding all loading, service and travel times along the path from 0 to  $j$ . If  $h_{p'} < a_j$ , then  $h_{p'}$  is set to  $a_j$  (waiting is allowed).
- $W_{p'}^j = 1$  and  $W_{p'}^g = W_p^g, \forall g \in V' \setminus j$
- To compute the minimal trip duration  $d_{p'}^{min}$  of  $L_{p'}$ , the waiting time is reduced as much as possible by delaying the departure time from depot to the latest possible date.
- To compute the time window of label  $L_{p'}$ , the maximum advancement and the maximum retardation of the label is computed, such that none of time constraints at customers is violated. The updated start and end of label's time window are thus obtained.

As for dominance, we use the following relation:

##### Definition 4.5 *Dominance relation*.

If  $p$  and  $p'$  are two different paths from origin 0 to node  $j$  with labels  $L_p$  and  $L_{p'}$ , respectively, then  $p$  dominates  $p'$  if and only if the nodes visited by  $p$  and by  $p'$  are the same ( $W_p^i = W_{p'}^i$  for every customer  $i$ ), the time window of  $L_p$  includes the time window of  $L_{p'}$  ( $\mathcal{A}_p \leq \mathcal{A}_{p'}$  and  $\mathcal{B}_p \geq \mathcal{B}_{p'}$ ), and  $c_p \leq c_{p'}$ ,  $h_p \leq h_{p'}$ ,  $q_p \leq q_{p'}$ ,  $d_p^{min} \leq d_{p'}^{min}$ .

That is a path  $p$  dominates a path  $p'$  if (i) its cost  $c_p$  is not greater, (ii) it does not consume more resource for every resource considered, (iii) it visits the same customers and (iv) it has at least the same temporal positions.

**Lemma 4.1** *If label  $L_1$  dominates label  $L_2$  then for all labels  $L_4$  extended from  $L_2$  there is a label  $L_3$  which dominates label  $L_4$ .*

*Proof:*

Let  $L_1$  dominates  $L_2$  at node  $j$ . Then, we know that these two labels visit the same customers, the time window of  $L_1$  includes the time window of  $L_2$ ,  $c_1 \leq c_2$ ,  $h_1 \leq h_2$ ,  $q_1 \leq q_2$  and  $d_1^{min} \leq d_2^{min}$ . For every feasible label  $L_4$  arriving at node  $g$  at time  $h$  extended to  $L_2$ , there exists a feasible label  $L_3$  arriving at node  $g$  at time  $h$  extended to  $L_1$ , such that the nodes visited by  $L_3$  after the node  $j$  are the same, and are visited in the same order, than the nodes visited by  $L_4$  after the node  $j$ . If there was no label  $L_3$  with these properties, then either  $h_2 < h_1$ , the time window of  $L_1$  would not include the time window of  $L_2$  or  $d_2^{min} < d_1^{min}$ , and thus  $L_1$  would not dominate  $L_2$ . We note by  $path$  the partial path between  $j$  and  $g$ . The resource consumptions on this partial path are the same. Thus  $q_3 \leq q_4$  and  $L_3$  and  $L_4$  visit the same customers.

The reduced cost  $c_{path}$  and the minimal trip duration  $d_{path}^{min}$  along the path from  $j$  to  $g$  are the same for  $L_3$  and  $L_4$  because the nodes are visited in same order and at the same times. Thus, we can consider that the reduced cost of  $L_3$  is equal to  $c_1 + c_{path}$  and that the reduced cost of  $L_4$  is equal to  $c_2 + c_{path}$ . Consequently we have  $c_3 \leq c_4$ .

We can also consider that the minimal trip duration of  $L_3$  is equal to  $d_1^{min} + d_{path}^{min} + d_{wait_3}^{min}$  and that the minimal trip duration of  $L_4$  is equal to  $d_2^{min} + d_{path}^{min} + d_{wait_4}^{min}$  where  $d_{wait_3}^{min}$  (resp.  $d_{wait_4}^{min}$ ) is the minimal waiting time necessary to connect the path represented by  $L_1$  (resp.  $L_2$ ) and the path  $path$  for  $L_3$  (resp.  $L_4$ ).

We know that, due to the dominance,  $d_1^{min} + d_{path}^{min} \leq d_2^{min} + d_{path}^{min}$ . The question is to know if  $d_{wait_3}^{min} \leq d_{wait_4}^{min}$ . We know that the time window of  $L_1$  includes the time window of  $L_2$  and thus the arrival time to node  $j$  of  $L_1$  can be delayed until the arrival time to node  $j$  of  $L_2$ . Consequently the arrival time to node  $j$  of  $L_3$  can be delayed until the arrival time to node  $j$  of  $L_4$  and it follows that  $d_{wait_3}^{min} \leq d_{wait_4}^{min}$  and  $d_1^{min} + d_{path}^{min} + d_{wait_3}^{min} \leq d_2^{min} + d_{path}^{min} + d_{wait_4}^{min}$ .

Once cost and route duration have been checked, the last concern to obtain proof of our dominance relation lemma is time windows. We know that  $d_1^{min} \leq d_2^{min}$  and  $[\mathcal{A}_2, \mathcal{B}_2] \subseteq [\mathcal{A}_1, \mathcal{B}_1]$  so if we can consider that  $[\mathcal{A}'_1, \mathcal{B}'_1] = [\mathcal{A}_2, \mathcal{B}_2]$  as the time window for  $L_1$  then if we add  $path$  to  $L_2$  and  $path$  to  $L_1$  with this time window, we obtain  $[\mathcal{A}'_3, \mathcal{B}'_3] = [\mathcal{A}_4, \mathcal{B}_4]$  as time windows for  $L_3$  and  $L_4$ . Since, we have  $[\mathcal{A}_2, \mathcal{B}_2] = [\mathcal{A}'_1, \mathcal{B}'_1] \subseteq [\mathcal{A}_1, \mathcal{B}_1]$  thus the time windows of  $L_3$  will include  $[\mathcal{A}'_3, \mathcal{B}'_3]$  and we will have  $[\mathcal{A}_2, \mathcal{B}_4] \subseteq [\mathcal{A}_3, \mathcal{B}_3]$ .

Thus we have  $c_3 \leq c_4$ ,  $h_3 \leq h_4$ ,  $q_3 \leq q_4$  and  $d_3^{min} \leq d_4^{min}$  and the time window of  $L_3$  includes the time window of  $L_4$  then label  $L_3$  dominates  $L_4$ .

◇◇◇

The labeling and dominance process can be illustrated with the example given in Figure 1. In this example, the node  $D$  represents the depot and nodes 1,2,3,4 the customers.  $\alpha$  is equal to 3 and the costs marked on arcs take this value into account. The demand and the service time at each customer are set to 0.

Let us compare two labels  $L_1$  and  $L_2$ , with the following values (see definition 4.4):  $L_1 = \{-5, 3, 6, 0, 4, 2, 8, 1, 1, 1, 0\}$ ,  $L_2 = \{-5, 3, 6, 0, 4, 2, 6, 1, 1, 1, 0\}$ .  $L_1$  and  $L_2$  visit respectively nodes 2,1,3 and nodes 1,2,3, in these orders. Thanks to our dominance relation,  $L_1$  dominates  $L_2$  at node 3. In this example, if we extend  $L_2$  to node 4, we obtain a label  $L_4$  such that  $L_4 = \{-7, 4, 7, 0, 5, 2, 7, 1, 1, 1, 1\}$  and  $L_4$  visits nodes 1,2,3,4 in this order. If we extend  $L_1$  to node 4, we obtain a label  $L_3$  such that  $L_3 = \{-7, 4, 7, 0, 5, 2, 9, 1, 1, 1, 1\}$  and which visits nodes 2,1,3,4 in

Figure 1: Illustration of dominance relation

this order.  $L_3$  visits the same nodes as  $L_4$ , it has the same cost, time, load and minimal trip duration as  $L_4$  but its time window includes the time window of  $L_4$ . Thus  $L_3$  dominates  $L_4$ .

This lemma ensures that the dominance relation, defined in Definition 4.5, does not delete labels that could potentially contribute to the optimal solution.

Please note that the atteignability of clients is implicitly included in our definitions, thanks to the combination of explicit resources.

### 4.3 Column Generation

The second phase of the algorithm is based on Column Generation and Branch and Price. We propose a set covering formulation where columns (variables) represent trips (see Definition 4.3).

#### Master problem formulation:

The itinerary to planify for a vehicle consists in a set of successive trips. Two trips of a given vehicle cannot overlap in time. We partition the planning horizon in a set of time intervals  $\Delta_t$ . During each  $\Delta_t$ , at most  $U$  vehicles should be used.  $\Delta_t$  is defined by  $\Delta_t = [l_{min} * t, l_{min} * (t + 1)[$  where  $l_{min}$  is a small value guaranteeing that the duration of any trip will be greater than  $l_{min}$ , and  $t \in \{0, \dots, \lfloor \frac{T}{l_{min}} \rfloor\}$ . The set of variables is denoted  $\Omega$ . With these assumptions we can formulate the master problem as follows:

$$z(\Omega) = \underset{r_k \in \Omega}{\text{minimize}} \sum c_k \theta_k \quad (26)$$

subject to

$$\sum_{r_k \in \Omega} a_{ik} \theta_k \geq 1 \quad (v_i \in V \setminus \{v_0\}), \quad (27)$$

$$\sum_{r_k \in \Omega} b_{tk} \theta_k \leq U \quad (\forall \Delta_t), \quad (28)$$

$$\theta_k \geq 0 \quad (r_k \in \Omega), \quad (29)$$

where  $c_k$  is the cost of trip  $r_k$ ,  $a_{ik}$  indicates whether customer  $i$  is visited by trip  $r_k$  or not,  $b_{tk} \in [0, 1]$  is the fraction of the time interval  $\Delta_t$  occupied by trip  $r_k$  and  $\theta_k$  are decision variables. Constraints (27) enforce that every customer is visited at least once. For each trip  $r_k$ ,  $\sum_t b_{tk} > 1$ . This is true because the length of any interval is inferior to the duration of any trip. Thus, constraints (28) enforce that at most  $U$  vehicles are used during any time interval.

In practice, this model contains a huge number of variables. We propose to solve it using a Branch and Price algorithm. Branch and Price is a special case of Branch and Bound where bounds are computed using a Column Generation technique. The Column Generation principle, explained in Feillet (2007) (see also Desrochers et al. (1992)), consists in decomposing the whole problem into a master problem and a subproblem. This technique is an iterative process that alternately solves a restricted master problem and a subproblem.

For each iteration  $w$ , the restricted master problem corresponds to the linear relaxation of the model restricted to a subset  $\Omega_w$  of its variables  $\Omega$ . It is solved by a simplex algorithm to provide primal and dual variable values.

The subproblem consists in finding the negative reduced cost variables in the master problem variable set. These variables are added to the variable set of the restricted master problem before beginning another iteration. Only trips  $r_k$  with a negative reduced cost can possibly decrease the cost of the current solution. The process stops when the subproblem cannot generate any negative reduced cost variable.

The dual of the master problem is given hereafter:

$$y(\Omega) = \text{maximize} \quad \sum_{i \in V \setminus \{0\}} \lambda_i - U \sum_t \mu_t \quad (30)$$

subject to:

$$\sum_{i \in V \setminus \{0\}} a_{ik} \lambda_i - \sum_{\Delta_t} b_{tk} \mu_t \geq c_k (r_k \in \Omega) \quad (31)$$

$$\lambda_i \geq 0 \quad (32)$$

$$\mu_t \geq 0 \quad (33)$$

### The subproblem:

The subproblem consists in finding trips (structure fixed in time) with a negative reduced cost  $c_k - \sum_{i \in V \setminus \{0\}} a_{ik} \lambda_i + \sum_{\Delta_t} b_{tk} \mu_t$ , where  $\lambda_i$  and  $\mu_t$  are dual variables respectively corresponding to primal constraints (27 and 28). For the set of trips corresponding to a common given structure, only time position varies and affects the reduced cost. Every non-dominated structure has been previously enumerated (set  $S$ ). Thus, the subproblem consists in finding, for every structure  $s_k$ , new trips, which are generated by selecting a time position in the time window  $[\mathcal{A}_k, \mathcal{B}_k]$  and kept as new columns only if their reduced cost is negative. In fact, for a given structure, only the trip with the lowest negative reduced cost is kept as new column.

In order to find this time position, we have created a scheduling sub-algorithm. For each structure  $s_k$  in  $S$ , our algorithm translates  $s_k$  in its time window by unit time steps and computes the reduced cost of associated trip. Please note that the length of unit time step corresponds to the time granularity of the instance and is not to be confused with the length of a time interval. As soon as a negative reduced cost is obtained, translation stops. Otherwise translation stops when all possible temporal positions within the time windows of  $s_k$  have been tried. This algorithm has a polynomial-time complexity.

When no such columns can be found, the Column Generation process stops.

Figure 2: Branching strategy

#### Initialization process:

An initial solution is required in order to start the Column Generation process. Finding an initial solution might be not trivial or even impossible, as the fleet is limited. We thus create an initial "Super-trip" that visits all customers and associate a great cost to this trip. The Super-trip is generally not feasible for the real problem but it satisfies the master problem.

**Definition 4.6 *Super-trip*** Let  $r^*$  be the trip with cost  $c^* = 2 \sum_{r_k \in \Omega} c_k$ .  $r^*$  contains all the customers, its time windows is equal to the depot time windows and all  $b_{tk}$  are equal to the number of vehicles allowed.

#### 4.4 Branch and Price scheme

Column Generation is applied at each node of a search tree generated by the Branch and Price algorithm to compute a lower bound. Classically, when solving VRPTW, the branching is made on arcs' flows. This scheme is used because the alternative to branch on selection of routes for the clients' set covering would often cause the branching tree to be badly equilibrated which would result in poor performance. Our algorithm also involves branching on arcs. Nevertheless, in our case and unlike for VRPTW, because of temporal constraints, having all arcs with an integer flow does not imply that the solution (set of  $\theta_k$ s) is integer. Then, once all arc flows are integer on a given node, we apply a repair strategy, which provides a simple rescheduling functionality without changing solution cost and which is explained below. If the repair algorithm does not succeed, we branch on arcs that have not been directly forced by the branching till then but were made integer as a consequence of the optimization process. Figure 2 illustrates this principle.

#### Branching scheme on arcs:

The branching is applied on an arc  $(i, j)$  if its flow is fractional. Two branches are created: one branch with  $x_{ij} = 1$ , where customer  $j$  must be visited immediately after customer  $i$ , and one

branch with  $x_{ij} = 0$  otherwise. In the first case, all arcs  $(k, j)$  and  $(i, k)$ , with  $k \neq j \neq i$ , are forbidden and all corresponding  $x_{kj}$  and  $x_{ik}$  are fixed to 0. To update the set of variables of the restricted master problem, all  $\theta_k$  representing the route  $r_k$  that use an arc  $(i, j)$  with the associated  $x_{ij} = 0$ , are set to zero.

### Repair strategy:

When all arc flows are integer, the set of arcs containing units of flow is the same as the set of arcs which compose the structures (see Definition 4.2) of trips selected in current candidate solution. In this case and when the candidate solution is fractional, at least one of these structures appears at least twice in the set of selected trips, at two different temporal positions. The repairment consists in rescheduling in order to obtain an integer solution for this node if there is one.

From the scheduling theory standpoint, we may define the problem as a set of  $N$  tasks  $\mathcal{T} = \{\mathcal{T}_1, \dots, \mathcal{T}_N\}$  such each  $\mathcal{T}_i$  (representing the structure  $s_i$ ) admits a release date  $r_i$  ( $\mathcal{A}_i$ , the beginning of time window of the structure  $s_i$ ) a deadline  $\tilde{d}_i$  ( $\mathcal{B}_i$ , the end of time window of structure  $s_i$ ) and a duration  $p_i$  ( $d_i^{min}$ , the minimal trip duration for structure  $s_i$ ). So, the starting time of  $\mathcal{T}_i$  must be after the release date and the completion time must be before  $\tilde{d}_i$ . For this scheduling analysis, let us restrict the problem to a single vehicle case, or equivalently for scheduling, to a single processor. Let  $\mathcal{T}_i$  and  $\mathcal{T}_j$  be two tasks then  $[t_i, t_i + p_i] \cap [t_j, t_j + p_j] = \emptyset$  with  $t_i$  designs the starting time of task  $\mathcal{T}_i$ . The aim is to find a feasible schedule. We will suppose that each task admits a height of size one. We denote this problem as  $\Pi$ .

The integer constraints are relaxed: at time  $t$ ,  $x\%$  of a route  $k$  may be consumed by a vehicle  $u$ , and  $y\%$  by another vehicle  $u'$ . Then, we define the fractional problem of  $\Pi$  as follows:

**Definition 4.7** *A feasible fractional solution of the problem  $\Pi$  is a relaxation on the height integer value:  $\exists \mathcal{T}_i$  such that*

- $t_{i_1} \leq t_{i_2} \leq \dots \leq t_{i_k}$  such that  $r_i \leq t_{i_1}$  and  $t_{i_k} + p_i \leq \tilde{d}_i$ ;
- Let  $h_{i_1}, h_{i_2}, \dots, h_{i_k}$  be the fractional height of the tasks  $\mathcal{T}_i$  with  $\sum_{j=1}^k h_{i_j} = 1$ .

Notice that with this definition several tasks may be executed at time  $t$ . Nevertheless, the sum of height-tasks processed at time  $t$  cannot be greater than one.

**Remark:** A feasible fractional solution may not imply a feasible integer solution. To demonstrate this, let us consider the following instance:

- $\mathcal{T}_1$  with  $p_1 = 2, r_1 = 6$  and  $\tilde{d}_1 = 10$ ;
- $\mathcal{T}_2$  with  $p_2 = 2, r_1 = 1$  and  $\tilde{d}_2 = 5$ ;
- $\mathcal{T}_3$  with  $p_1 = 6, r_1 = 0$  and  $\tilde{d}_3 = 11$ ;

Consider the feasible fractional solution given by the Figure 3.

- $t_{1_1} = 6, t_{1_2} = 8$
- $t_{2_1} = 1, t_{2_2} = 3$
- $t_{3_1} = 0, t_{3_2} = 5$
- and  $\forall i, j, h_{i_j} = 1/2$

Figure 3: A counter-example for the non-existence of a feasible integer solution from a feasible fractional solution

There is no feasible integer solution:

- If the first scheduled task is  $\mathcal{T}_3$  then the constraints cannot be respected for task  $\mathcal{T}_2$ .
- If the first scheduled task is  $\mathcal{T}_2$  then the lower bound for the starting time for task  $\mathcal{T}_1$  is 3. So the completion time of the task  $\mathcal{T}_3$  is at least 9. The deadline for  $\mathcal{T}_1$  is not respected.

The complexity of assessing the existence of a feasible integer solution is given by Theorem 4.1.

**Theorem 4.1** *The problem of assessing the existence of an integer feasible solution for the problem  $\Pi$  is  $\mathcal{NP}$ -complete.*

*Proof:*

The problem of existence of a feasible integer solution is  $\mathcal{NP}$ -complete. Indeed, the problem  $\Pi$  is exactly the same as the scheduling problem denoted by  $1|p_i, r_i, \tilde{d}_i|C_{max}$ <sup>1</sup> for the minimization of  $C_{max} = \max_i \{t_i + p_i\}$  which is proved  $\mathcal{NP}$ -complete, see Lenstra et al. (1977).

◇◇◇

Note that there exists a Branch and Bound algorithm for solving  $1|p_i, r_i, \tilde{d}_i|C_{max}$  problem, see Bratley et al. (1971) and Blazewicz et al. (2007). We do not hold this method back, since the aim is to develop a method for a constant limited number of vehicles not only for a single vehicle.

In fact, this scheduling problem is similar to the VRPTW. At this node of the Branch and Price tree, there is a set of structures with their time windows and durations. Note that, unlike the VRPTW customers, the structure must be processed before the end of its time window  $[\mathcal{A}_k, \mathcal{B}_k]$  thus the end is replaced by  $\mathcal{B}_k - d_k^{min}$ . With this simple modification, we have a VRPTW instance in which customers correspond to timed structures, customer demands are equal to 0 and distances (resp. costs) between two customers  $i$  and  $j$  are equal to the travel distance of structure  $s_j$  (resp. the cost of structure  $s_j$ ). In order to solve this VRPTW, we use the Branch and Price algorithm described in Desrochers et al. (1992). Note that the Branch and Price algorithm is very fast. This is due to the fact that the cost of the optimal solution at root node is the same as the cost of the optimisation solution for the node where an integer solution is found.

---

<sup>1</sup>In scheduling theory, the problems are characterized by the *three fields* notation scheme  $\alpha|\beta|\gamma$ , proposed by Graham et al. (1979), where  $\alpha$  designates the environment processors,  $\beta$  the characteristics of the job and  $\gamma$  the criteria.

### Remark about pruning:

The way we have defined the initial solution of master problem (Super-trip) allows to prune some branches during the Branch and Price process thanks to the following lemma:

**Lemma 4.2** *If the Super-trip  $r^*$  is present in the optimal Master Problem solution at the current node, then there is no integer solution that does not contain the trip  $r^*$  in the subtrees of this node.*

The proof of this lemma is out of the scope of this paper and is given in Hernandez (2010).

From this Lemma, it is possible to prune the branching tree when the subtree of the current node does not contain an integer solution other than the Super-trip. Our algorithm implements this pruning condition which has proved effective during the tests on Solomon's instances.

## 5 Results

### 5.1 Presentation

In this section, many results obtained with our exact algorithm are reported. First, the test instances of Solomon are presented, and we give the results for these instances, with 25 and 50 customers. Then, we analyse the impact of phase 1 dominance rule on Solomon's instances with 25 customers. The impact of limit duration and time windows is also investigated. The computing platform is a Pentium 4 2.0 GHz with 2 GB of RAM using GLPK to solve the master problem. The comparison with results in Azi (2010) is given in the following section.

### 5.2 Test instances

Our tests were performed using the well-known VRPTW benchmark instances created by Solomon (1987). These instances are divided into six classes that are a combination of two criteria. The first criterion concerns the spatial position of customers. There are three different spatial layouts: customers in clusters ("C" type), customers randomly located ("R" type), and intermediate case with part of customers clustered and the rest randomly located ("RC" type). The second criterion concerns the tightness of time constraints at customers. There are two types: tight time windows and small planning time (type "1") and large time windows and planning time (type "2"). Combining these two criteria, there are six basic classes which are denominated: "C1", "C2", "R1", "R2", "RC1" and "RC2". In total, there are 56 instances with 100 customers. Please note that for a given class, there are several instances with different customer time windows, but the spatial layout of customers is the same for the whole class. Instances are denoted as in following example: C201-25 correspond to the first instances of class "C2" where only the first 25 customers are considered. In this study, instances with tight planning time horizon were discarded. In fact, the short horizon does not allow a significant number of routes to be affected to the same vehicle. For these results, due to the difference between the service time of the instances of class C2 and the service time of instances of classes R2 and RC2, two different  $t_{max}$  values were tested. For instances of classes R2 and RC2,  $t_{max}$  were set to 75 and 220 for instances of class C2. Finally, for all tests, the parameter  $\beta$  for the trip loading time was set to 0.2 and the limit computation time was fixed to 30 hours.

### 5.3 Results on Solomon's benchmark

We close 25 of the 27 Solomon's instances with 25 customers and large time horizon and 2 vehicles and 22 of the 27 with 50 customers with large time horizon and 4 vehicles. The last 7

Table 1: Results on the Solomon’s benchmark (25 customers) with  $t_{max}$  value set (75; 220)

instances have not been solved within a limit on computing time set to 30 hours.

Tables 1 and 2 present these results. For each instance, we have the root solution cost and the solution cost of the Branch and Price scheme used in Phase 2, the computation time for both phases (Total time), the computation time of Branch and Price root in Phase 2 (Root time), the computation time of Phase 1 (Phase1 time), the number of iteration (iter) and the number of generated columns (column).

We can note, as for the VRPTW, there is great variation for time resolution between instances of the same class. We can also note a significant increase of total computation time between the instances with 25 and 50 customers.

#### 5.4 Impact of the dominance rule in phase 1

In this section, we evaluate the impact of the dominance rule when feasible trips are generated with the elementary shortest path algorithm with resource constraints in Phase 1. The number of available vehicles ( $U$ ) was set to 2 for these tests.

In Table 3, for each instance, we compare the following criteria : the number of generated structures in Phase 1 (# trips), the computation time for both phases (Total time) and the computation time of Phase 1 (Phase1 time), with (Dom) and without (No Dom) dominance

Table 3: Impact of dominance rule with  $t_{max}$  value set (75;220)

rule. For each criterion, we present the ratio (Ratio) between the case with dominance rule and the case without dominance rule. A "—" in the table indicates that the corresponding instance could not be solved.

We can check that the solution costs are not affected by the dominance relation. The rc207-25 instance is closed with dominance rule and not without. The bottom line of this table contains the sum of computation time for both phases, computation times of Phase 1 and number of generated structures in Phase 1. Note that, due to rc207-25 not being closed without dominance rule, the sum of computation time for both phases excludes this instance. As we can see, if we do not apply the dominance rule, the number of generated trips are increased by approximately 12%, the computation time of phase 1 is increased by 7% and the total computation time is increased by 87%.

Table 4 presents the same comparison with a larger  $t_{max}$  value set. This value is set to 100 for instances of classes R2 and RC2 and to 250 for instances of class C2. Without applying the dominance rule, the number of generated structures is increased by 37%, the Phase 1 computation time is three times longer and the total computation time is increased by 30%. A "—" in the table indicates that the corresponding instance could not be solved. We can note that the impact of dominance rule is higher for a larger  $t_{max}$ , due to the increase of the number of feasible structures.

## 5.5 Impact of duration limit

In this section, we evaluate the impact of duration limit.  $U$  is set to 2. In Table 5, we compare the following criteria for each instance: the solution cost, the total computation time, including both phases (Total time), the computation time of Phase 1 (Phase1 time) and the number of generated structures in Phase 1 (# trips) for two couples of  $t_{max}$  values (75;220) and (100;250).

Table 4: Impact of dominance rule with  $t_{max}$  value set (100;250)

We give the ratio between each criterion for  $t_{max}$  (75;220) and same criterion for  $t_{max}$  (100;250). A "—" in the table indicates that the corresponding instance could not be solved. Note that we have chosen these values for the purpose of comparing our results with the results presented in Azi (2010).

As expected, the solution cost decreases when duration limit increases. It can be observed that increasing the duration limit does not necessarily increase the total computation time. Indeed, the main time consumption is generated by the second phase and the difficulty of the covering problem is not necessarily correlated with the trip length.

We note an important decrease of the total computation time for the instance rc207-25 and an important increase for the instance r207-25. Because of these peculiarities, we distinguish two total sums, one that includes these special instances denoted Total and an other without them denoted Total\*. We have an increase of 300 % of the total computation time for Total\* and a decrease of 90 % for Total.

Also, for both Total and Total\*, we can see an increase of 2200 % in computation time of Phase 1 and an increase of 450 % of Phase 1 generated trips. Indeed the maximal number of visited customers per feasible trip has an important impact on the dynamic programming and the number of generated labels. However, this does not affect much the total computation time, as the Phase 1 computation time is rather small.

## 5.6 Impact of time windows

In this section, we evaluate the impact of the length of time windows.  $U$  is set to 2. For this purpose, we have reduced the length of customer time windows by half. Four means of reducing this length have been used. In the first case (denoted Type 1), we compute the center  $c_i$  of each customer time window as follows  $c_i = \frac{a_i + b_i}{2}$  and we set its new start  $a'_i$  (resp. new end  $b'_i$ ) to

Table 5: Impact of  $t_{max}$  value set on the Solomon’s benchmark (25 customers)

the value  $\frac{a_i+c_i}{2}$  (resp.  $\frac{b_i+c_i}{2}$ ). For the second case (denoted Type 2), we compute  $c_i = \left\lfloor \frac{a_i+b_i}{2} \right\rfloor$  and we set  $a'_i$  (resp. new end  $b'_i$ ) to the value  $\frac{a_i+c_i}{2}$  (resp.  $\frac{b_i+c_i}{2}$ ). For the third case (denoted Type 3), we compute  $c_i = \frac{a_i+b_i}{2}$  and we set  $a'_i$  (resp. new end  $b'_i$ ) to the value  $\left\lfloor \frac{a_i+c_i}{2} \right\rfloor$  (resp.  $\left\lfloor \frac{b_i+c_i}{2} \right\rfloor + 1$ ). For the last case (denoted Type 4), we compute  $c_i = \left\lfloor \frac{a_i+b_i}{2} \right\rfloor$  and we set  $a'_i$  (resp. new end  $b'_i$ ) to the value  $\left\lfloor \frac{a_i+c_i}{2} \right\rfloor$  (resp.  $\left\lfloor \frac{b_i+c_i}{2} \right\rfloor + 1$ ). As a last experiment (denoted Without), we have relaxed all customer time windows, that is, we have assigned the time window of the depot to each customer. In this case, only three instances were considered, one for each class because there is only one spatial layout for each class.

In Table 6, for each instance, we compare the solution cost, the total computation time of the two phases (Total time) and the computation time of Phase 1 (Phase1 time), for the basic case and the reduced time windows of Type 1. A "no sol" in the table indicates that the corresponding instance does not have a solution for this setting.

All instances with 25 customers are closed. As expected, the solution cost increases with reduced time windows, and 8 instances have no solution in this setting. The solution time of these instances are very small thanks to the application of the Lemma 4.2. We can also see, unlike the effect observed in Azi (2010), that this reduction does not necessarily decreases the total computation time.

In Table 7, for each instance, we present the solution cost and the total computation time for the different reduction types. As a first finding, c201-25 gets a solution for reduction Types 3 and 4 and not for Types 1 and 2. We can also note for types 3 and 4 that the solution cost can decrease with these little modifications of time windows. By using two different types of time windows reduction, a maximum variation of 2 time units is obtained for a given client. This

Table 7: Comparison results on the Solomon’s benchmark (25 customers) with different types of reduced time

corresponds to about 1% of time horizon for instances of classes and r2 rc2 and about 0.3% for instances of the class c2. Thus, we can note that this problem is indeed very sensitive to time windows.

Finally, in Table 8, we present the results obtained when we relax the time windows of customers. We note that only three instances are considered, one for each class. For each class, as for the case without time windows (Without), we present the solution cost, the total resolution time and Phase 1 resolution time. As for the basic case, we give, for each class, the cost for the instance with cheapest solution, the total resolution time for the instance with highest total resolution time, and the Phase 1 resolution time for the instance with highest Phase 1 resolution time. We also give, for each class, and for total resolution time and Phase 1 resolution time, the ratio of the value obtained in the basic case on the value obtained in the no time window case.

Firstly for Table 8, the instance rc2XX-25 is not solved. Secondly, the solution cost of the no time window case is a lower bound of the solution cost of all this class’ instances. The total resolution time is lower than the highest resolution time of each class unlike the Phase 1 resolution time, which is always higher.

Instance	Solution		Temps total			Temps phase 1		
	Without	Basic	Without	Basic	Ratio	Without	Basic	Ratio

r2XX-25	574.23	575.91	25.031	25.805	1.03	0.141	0.078	0.55
rc2XX-25	-	-	-	-	-	-	-	-

Table 8: Comparison of results obtained with no window of time and without reduction on the Solomon’s benchmark with  $t_{max}$  value set (75;220) and no time windows

The above results show that the time windows, their length and their time positions, have much impact on the solution existence and the solution cost. We can also note that, still, the resolution times of Phase 1 increase when the size of time windows increases. This is due to the dynamic programming used during this phase and the fact that the structure search space is larger.

## 6 Discussion

### 6.1 Comparison to previous results on this problem

Table 9 gives, for each instance, the cost of the optimal solution found, the total solving time with  $t_{max}$  set to (75; 220). The comparison between our results and those obtained in Azi (2010) is given for all these data. Recall that results in Azi et al. (2010) were corrected in Azi (2010), thus explaining that we only compare with the latter. For the total solving time, the following ratio is also provided: processing time in Azi (2010) divided by processing time of our method.

We can distinguish two categories among instances: (i) those for which we find the same optimal cost and (ii) the ones which we close and which were not closed in Azi (2010).

17 of the 27 Solomon instances with 25 clients and a large time horizon fall in the first category. In these cases, we get significantly faster results, up to 25000 times faster, and 1000 times faster in average.

As for the second category, and with an available fleet size of 2, we provide an optimal solution for the instances c202-25, c203-25, c204-25, c206-25, c207-25 and c208-25 with  $t_{max} = 220$  and for the instances rc202-25, rc203-25 and rc207-25 with  $t_{max} = 75$ .

Table 10 gives, for each instance, the cost of the optimal solution and the total solving time for  $t_{max} = (100; 250)$ . Like in Table 9, the comparison between our results and those obtained in Azi (2010) is given. The numerator of the ratio is the solving time in Azi (2010) and its denominator is the solving time provided by our method.

We can use the same 2 categories as above for the shorter  $t_{max}$ .

In the first category, we find 17 of the 27 Solomon instances with 25 clients and a large time horizon. Like for the smaller  $t_{max}$  case, our method is 1000 times faster on average for these instances than the method in Azi (2010), and the ratio varies between 5 times faster to 10000 times faster.

As for the second category, and with an available fleet size of 2, we provide an optimal solution for the instances c202-25, c203-25, c207-25 and c208-25 with  $t_{max} = 250$  et and for the instances r204-25, r207-25, r208-25, r211-25, rc203-25 et rc207-25 with  $t_{max} = 100$ .

## 6.2 Analysis of performance in regards to master problem formulation

We obtain a clear enhancement in solving time for the instances solved. To analyse this ameliorated performance, we should compare the formulation of the master problem in the column generation used in Azi et al. (2010) and Azi (2010) compared to ours. In these works, the variables of the master problem are workdays which correspond to a succession of trips. The computation of a workday involves to select a number of trip timed structures and to associate to each trip a temporal position, as well as a successor and a predecessor. The variables of our master problem are trips, with time position but no need to associate successor and predecessor. The size of the variables' set of our master problem is then much smaller than in Azi et al. (2010) and Azi (2010). Our subproblem needs then to search a smaller space to find a variable with negative reduced cost.

Furthermore, finding a workday with negative reduced cost implies to solve an ESPPRC as the subproblem. With our own variable definition, we can avoid the ordering part of this problem, and only need to find the best temporal position for each timed structure. Thus, we could provide a pseudo-polynomial complexity to our subproblem. The task of ordering trips is handled by the constraint 28 in the master problem.

The combination of these two differences, smaller variables' set and subproblem with reduced complexity, explains the clear reduction observed in the solving times.

## 7 Conclusion and future research

In this paper, we addressed the exact solution of the MTRPTW-LD, previously introduced and investigated in Azi et al. (2010). We proposed an efficient branch and price scheme, achieving a fast improvement compared to Azi (2010) with regard to computing times. A main advantage of our approach lies in the efficiency of the Column Generation subproblem, solved with a fast pseudo-polynomial algorithm. The future research is to extend the previous scheme to the general problem without limited duration.

## Acknowledgment

We acknowledge Cemagref and Région Languedoc-Roussillon in France for providing the basic funding of this research, as well as contributions from LIRMM, PNRB MOBIPE project supported by french ANR, and A2PV SyDeReT project. We thank Pr J.C. König for finding the counter exemple given in section 4.4.
